

Bounds smaller than the Fisher information for generalized linear models

Lixing Zhu* and Zhenghui Feng

Department of Mathematics, Hong Kong Baptist University, Hong Kong, China

Abstract

In this paper, we propose a parameter space augmentation approach that is based on “intentionally” introducing a pseudo-nuisance parameter into generalized linear models for the purpose of variance reduction. We first consider the parameter whose norm is equal to one. By introducing a pseudo-nuisance parameter into models to be estimated, an extra estimation is asymptotically normal and is, more importantly, non-positively correlated to the estimation that asymptotically achieves the Fisher/quasi Fisher information. As such, the resulting estimation is asymptotically with smaller variance-covariance matrices than the Fisher/quasi Fisher information. For general cases where the norm of the parameter is not necessarily equal to one, two-stage quasi-likelihood procedures separately estimating the scalar and direction of the parameter are proposed. The traces of the limiting variance-covariance matrices are in general smaller than or equal to that of the Fisher/quasi-Fisher information. We also discuss the pros and cons of the new methodology, and possible extensions. As this methodology of parameter space augmentation is general, and then may be readily extended to handle, say, cluster data and correlated data, and other models.

In this research, the methodology was developed and material organization of the manuscript was done by the first author. This manuscript is an updated version of the first manuscript that was submitted to arXiv: submit/0041278 on May 15, 2010. A special thank goes to Dr. Bing Li who has had intensive and stimulative discussions with us so that we have a deeper thinking on possible super-efficiency.

1 Introduction

For parametric regression models, efficiency of estimation is used as a criterion for estimation accuracy and is a well investigated issue, and relevant theories have been well developed in the literature. For instance, for linear models, when the design is fixed, Gauss-Markov theorem shows that the ordinary least squares estimation is the best linear unbiased estimation (BLUE, Markoff 1912). Plackett (1949) had a nice description on the contributions by Gauss, Laplace, Markov and others. Here ‘Best’ means minimum variance. When the design is random, its limiting variance achieves the Fisher information. However, the unbiasedness of estimation is usually not achievable, particularly for generalized linear models (GLMs), a notion about ‘best’ that can be explained for asymptotically unbiased estimation is also the Fisher information.

The Fisher information is a way of measuring the amount of information that an observable random variable carries about an unknown parameter upon which the probability of the observable random variable depends. Fisher (1922, p.316) presented the “Criterion of Efficiency” that refers to large-sample behavior: “when the distribution of the statistic tends to normality, that statistic is to be chosen which has the least probable error.” “Efficiency” is efficiency in summarizing information in the large-sample case.

The class of generalized linear models (GLMs) is one of the most widely used classes of regression models for statistical analyses. The relevant theoretical investigations are rather complete and the results of parameter estimation have been the standard results in the literature and textbooks. As is well known, the GLM is of a structure as

$$h(\mu) = \beta_0^T X \tag{1.1}$$

where $\mu = E(Y|X)$, Y is the response and X is the predictor vector of p dimension, β is the parameter of interest, and h is a given link function. It is also often written as

$$Y = g(\beta_0^T X) + \varepsilon, \tag{1.2}$$

with $E(\varepsilon|X) = 0$ and a given function g although (1.1) and (1.2) are not exactly equivalent unless g is invertible. Without loss of generality, assume that $E(X) = 0$ throughout the present paper.

Suppose that an independent identically distributed sample $\{(x_1, y_1), \dots, (x_n, y_n)\}$ is available. To estimate the parameter β , there are several standard methods and among them, the weighted least squares and the quasi-likelihood proposed by Wedderburn (1974) are the most popularly used methods when the distribution of error

is not parametric. The estimation of β via the quasi-likelihood can achieve the asymptotic efficiency: when the underlying distribution of error is natural exponential, the limiting variance-covariance matrix can be, or be proportional to, the Fisher information that attains the Cramér-Rao lower bound (Cramér, 1946; Rao 1945). In effect, it is asymptotically efficient among all consistent solutions to linear estimating equations, see Wedderburn (1974), McCullagh (1983), Jarrett (1984), McLeish (1984), Firth (1987) and Godambe and Heyde (1987). A relevant reference is Godambe (1960) who proved the optimum property of the Fisher information in the likelihood estimation. When we do not impose, other than some moments of the error, specific distributional conditions, the limiting variance-covariance matrix is called the quasi-Fisher information, see e.g. Wefelmeyer (1996). These results have long been benchmarks to be compared for estimation efficiency of any new method. Le Cam (1986) is a comprehensive reference book about rigorous proofs of the asymptotic optimality in this area. In recent years, some approaches were developed to improve generalized estimating equations by using quadratic inference functions for cluster data, see Li and Lindsay (1996) and Qu, Lindsay and Li (2000), and Wang and Qu (2009).

Note that all of existing estimation methods are within parametric framework. Nevertheless, this is a natural and seemingly necessary way for a parametric problem. As such, it seems that we may not need to bother ourself to estimate anything else other than the parameter of interest if there are no other nuisance parameters in the model. From a heuristic perspective in both practice and theory, if we did so, some extra estimation errors would be created and estimation variation would be even larger.

However, our study shows that this is not always true. In this paper, we propose a two-stage estimation method to estimate the scalar $\|\beta_0\|$ and the direction $\beta_0/\|\beta_0\|$ separately to form a final estimator of β_0 where $\|\cdot\|$ is the Euclidean norm. Although both the stages are based on the quasi-likelihood, the estimation for the direction $\beta_0/\|\beta_0\|$ is a semiparametric quasi-likelihood by introducing a pseudo-nuisance parameter into models to be estimated and regarding the link function g as its true value. In the next section, we will give a detailed motivation to describe why we do this. The results are interesting: the traces of the limiting variance-covariance matrices are smaller than or equal to those of the Fisher/quasi-Fisher information, and in some cases, particularly for β_0 with norm one, the matrices themselves are smaller than or equal to the corresponding Fisher/quasi-Fisher information. Also the reduction of variance is highly related to the correlations among the predictors. We will see this in the theorems in Section 4. Two relevant references are Wang, Xue, Zhu and Chong (2010) and Chang, Xue and Zhu (2010) about the least squares. Its special case is the linear model. Our result shows that although our estimation is only asymptotically unbiased, trace of the variance-covariance matrix is smaller than what Gauss-Markov theorem provided in independent identically distributed case. In the next section, we shall present the details of the estimation procedures

and the results. Of course, as a trade-off, to facilitate the use of nonparametric estimation, technical conditions on the predictor vector are much more stronger than those the classical methods need.

It is worth pointing out that this parameter-space augmentation approach has a root from the estimation problems with nuisance parameters. For example, Piece (1982) pointed out that when nuisance parameters in models are estimated, the estimation of the parameter of interest may be more efficient than that when nuisance parameters are regarded as given. The difference from his result is that as a methodology, we create a nuisance parameter to be estimated and regard the given link as its true value. This methodology may be useful for other estimation problems. We will have discussions in Section 5.

The paper is organized as follows. In Section 2, we shall in detail describe the motivation of our method. Section 3 presents the estimation procedures. Section 4 presents the results. As the results are related to given variance function of error and more regularity conditions than the classical quasi-likelihood needs for technical purpose, we shall in Section 5 discuss pros and cons of the new methodology and some extensions. The proofs of the main results are relegated to Section 6, the Appendix.

2 Motivation of methodology development

2.1 A brief review of the quasi-likelihood

For the model of (1.2), suppose that a sample $\{(x_1, y_1), \dots, (x_n, y_n)\}$ is available. In a simple case with a given variance function $v(X) = \text{var}(Y|X)$, the quasi-likelihood estimator $\hat{\beta}$ is the solution to the following equation

$$G(\beta) = \sum_{i=1}^n (y_i - g(\beta^T x_i)) g'(\beta^T x_i) x_i / v(x_i), \quad (2.1)$$

over all β . It is worth pointing out that for this $v(\cdot)$, the above is equivalent to weighted least squares (WLS). When the variance can be written as $\sigma^2 v(X)$ where σ^2 is an unknown dispersion parameter, we can still use $v(X)$ in the estimating equation. However, when $v(X)$ is of the structure $v(\beta_0^T X)$ or $v(g(\beta_0^T X))$, it is different from the WLS, and we will use it in $G(\beta)$ in the lieu of $v(X)$. As the proof is almost identical to the case with $v(X)$, and the results are also almost unchanged, even simpler in form, for the limiting variance of the estimator $\hat{\beta}$. Further, when function v of $v(g(\beta_0^T X))$ is also unknown, we need to use a nonparametric estimation

to replace it. The result is also similar. The extensions will be discussed in Section 5. Thus, we for simplicity of presentation use $v(X)$ throughout this paper.

From the projection theorem (Small and Mcleish, 1994, p. 79), the quasi-likelihood equation $G(\beta)$ of (2.1) is the optimal linear combination of $(y_i - g(\beta^T x_i))$'s. The asymptotic normality of $\hat{\beta}$ can be derived by using Taylor expansion and Slutsky theorem to obtain an asymptotic presentation as

$$\begin{aligned} & \frac{1}{\sqrt{n}} \sum_{i=1}^n \varepsilon_i g'(\beta_0^T x_i) x_i / v(x_i) \\ = & \left(\frac{1}{n} \sum_{i=1}^n (g'(\beta_0^T x_i))^2 / v(x_i) x_i x_i^T \right) \sqrt{n}(\hat{\beta} - \beta_0) + o_p(1) \\ =: & V \sqrt{n}(\hat{\beta} - \beta_0) + o_p(1). \end{aligned} \tag{2.2}$$

with $V = E\left((g'(\beta_0^T X))^2 / v(X) X X^T\right)$ and then

$$\sqrt{n}(\hat{\beta} - \beta_0) \Longrightarrow N(0, V^{-1}) \tag{2.3}$$

where “ $\Longrightarrow$ ” stands for convergence in distribution, and $V = E\left((g'(\beta_0^T X))^2 / v(X) X X^T\right)$. The matrix V^{-1} is called the quasi-Fisher information attaining the minimum among all estimations when we use the residuals $y_i - g(\beta^T x_i)$ to form linear combinations. Nevertheless, the above deduction is of course under certain regularity conditions.

2.2 Motivation: variance reduction by an extra “estimation”

To simplify the motivation for our estimation procedures in the next subsection, we give, for the time being, four assumptions among which the first three will be removed in the next section. First, assume $v(\cdot) = 1$ for the moment. Second, we consider for the time being the case where that β is of norm one: $\|\beta\| = 1$. This is because the following arguments do not make sense for general β due to identifiability problem. This is also the reason why we need two-stage estimation that will be described in the next section. Third, to reparametrize β when its norm is equal to one, we assume that we have a parameter θ of $p - 1$ dimension so that the $p \times (p - 1)$ Jacobin matrix $J(\theta) = \partial\beta/\partial\theta$ exists. The details will be presented in the next section as well. Forth, the dimension of β is greater than one, otherwise, our approach can improve nothing for the classical quasi-likelihood.

From the title of this subsection, it is a natural question to ask why and how we consider introducing an extra “estimation” when we use the quasi-likelihood. As

is known, the quasi-likelihood is motivated from the likelihood with given density function of the error, or the weighted least squares when the distribution of the error is unknown. For simplicity of illustration, we will consider the ordinary least squares (OLS) that is equivalent to the likelihood when the error term follows the standard normal distribution $N(0, 1)$.

2.2.1 Motivation from estimation criterion

The idea of the OLS is to search for a function $\tilde{g}$ with β so that $\tilde{g}(\beta^T X)$ can fit Y best in the OLS criterion. The basic probability theory tells us that the best $\tilde{g}(\beta^T X)$ should be the conditional expectation of Y given $\beta^T X$. Note that in the GLM $E(Y|\beta_0^T X) = g(\beta_0^T X)$ with respect to the joint distribution $F(x, y)$ of (X, Y) . Thus under the parametric framework, a natural choice is not to search for function $\tilde{g}$, while to use g and then to consider the class of $g(\beta^T X)$ over all β . Thus, the OLS criterion is defined as $M(\beta) = E(Y - g(\beta^T X))^2$ for any β . It is easy to see that the true parameter β_0 is the minimizer of $M(\beta)$ over all β because

$$E(Y - g(\beta^T X))^2 = E(\varepsilon)^2 + E(g(\beta_0^T X) - g(\beta^T X))^2.$$

The derivative of $M(\beta)$ with respect to θ leads to the population version of the estimating equation $G(\beta)$:

$$E\left(\varepsilon g'(\beta^T X) J(\theta)^T X\right) = E\left([g(\beta^T X) - g(\beta_0^T X)] g'(\beta^T X) J(\theta)^T X\right).$$

When the expectations in the both sides are replaced by their empirical versions that are based on the sample $\{(x_1, y_1), \dots, (x_n, y_n)\}$, we can obtain the estimating equation that is a special case of the quasi-likelihood. When β is close to β_0 at certain rate, θ close to θ_0 that is associated with β_0 , and $g'(\beta^T X) \approx g'(\beta_0^T X)$, the application of Taylor expansion yields that

$$\begin{aligned} & E\left(\varepsilon g'(\beta^T X) J(\theta_0)^T X\right) \\ & \approx E\left((g'(\beta_0^T X))^2 J(\theta_0)^T X X^T J(\theta_0)\right)(\theta - \theta_0). \end{aligned} \quad (2.4)$$

The limiting variance-covariance matrix of $\theta - \theta_0$ would be V^{-1} where

$$V = E\left(g'(\beta_0^T X)^2 J(\theta_0)^T X X^T J(\theta_0)\right).$$

Further, since $\beta - \beta_0 \approx J(\theta_0)(\theta - \theta_0)$, we can have that the limiting variance-covariance matrix of $\beta - \beta_0$ would be $J(\theta_0)V^{-1}J(\theta_0)^T$.

This method is entirely dependent on the parametric structure the model under study is of. As we mentioned above, at population level, β_0 is the minimizer

(solution) of $M(\beta)$ ($G(\beta)$), and $g(\beta_0^T X)$ is the conditional expectation $E(Y|\beta_0^T X)$. However, at sample level, the minimizer (solution) of the empirical version of $M(\beta)$ ($G(\beta)$) β is not exactly equal to the true value β_0 . As such, the search based on $M(\beta)$ is actually a directional search along the direction with the fixed g that is not necessarily equal to the conditional expectation of Y when $\beta^T X$ is given. This results in that the related minimum β may not attain the minimum that can be obtained by searching it in a larger subspace of functions $\{ \tilde{g}(\beta^T \cdot): \text{all } \tilde{g} \text{ and } \beta \}$. That is,

$$\begin{aligned} E(Y - g(\beta^T X))^2 &= E(Y - E(Y|\beta^T X))^2 + E(E(Y|\beta^T X) - g(\beta^T X))^2 \\ &\geq E(Y - E(Y|\beta^T X))^2 = \inf_{\tilde{g}} E(Y - \tilde{g}(\beta^T X))^2. \end{aligned}$$

This shows that the residual $Y - g(\beta^T X) = \varepsilon - (g(\beta^T X) - g(\beta_0^T X))$ may be of larger variability than $Y - E(Y|\beta^T X) = \varepsilon - (E(Y|\beta^T X) - g(\beta_0^T X))$ is of when $\beta \neq \beta_0$. It suggests that in the estimating equation, using $E(Y|\beta^T X)$ may lead an estimation of β_0 with less variability in terms of $(E(Y|\beta^T X) - g(\beta_0^T X)) \equiv (E(Y|\beta^T X) - E(Y|\beta_0^T X))$ than that in terms of $(g(\beta^T X) - g(\beta_0^T X))$. The application of Taylor expansion at β_0 gives us an expectation that $\beta - \beta_0$ obtained from the former would have smaller variance than this difference obtained from the latter. Then, we can consider the solution of

$$E\left((Y - E(Y|\beta^T X))\right)g'(\beta^T X)J(\theta)^T X = 0.$$

Equivalently, writing $E(Y|\beta_0^T X) = E(\varepsilon|\beta_0^T X) + E(g(\beta_0^T X)|\beta_0^T X)$,

$$\begin{aligned} &E\left(((\varepsilon - (E(Y|\beta_0^T X) - g(\beta_0^T X))))g'(\beta^T X)J(\theta)^T X\right) \\ &= E\left(((\varepsilon - E(\varepsilon|\beta_0^T X)) + (g(\beta_0^T X) - E(g(\beta_0^T X)|\beta_0^T X)))g'(\beta^T X)J(\theta)^T X\right) \\ &= E\left([E(Y|\beta^T X) - E(Y|\beta_0^T X)]g'(\beta^T X)J(\theta)^T X\right). \end{aligned} \quad (2.5)$$

Here we use the derivative g' of g rather than the derivative $E'(Y|\beta^T X)$ of $E(Y|\beta^T X)$ only because we try to avoid too many unknowns to be estimated. Note that in this presentation, although both of them are zero at population level we do not delete $E(\varepsilon|\beta_0^T X)$ and $(g(\beta_0^T X) - E(g(\beta_0^T X)|\beta_0^T X))$. This is because they are not necessarily zero at sample level, and will play an important role in variance reduction. When β is close to β_0 at certain rate, and also θ close to θ_0 that is associated with β_0 , noting that conditional expectation is a self-adjoint operator, and $g'(\beta^T X) \approx g'(\beta_0^T X)$, Taylor expansion for (2.5) yields that

$$\begin{aligned} &E\left(((\varepsilon - E(\varepsilon|\beta_0^T X)))g'(\beta^T X)J(\theta_0)^T X\right) \\ &\approx E\left(\varepsilon[g'(\beta_0^T X)(X - E(J(\theta_0)^T X|\beta_0^T X))]\right) \\ &\approx E\left((g'(\beta_0^T X))^2 J(\theta_0)^T X X^T J(\theta_0)\right)(\theta - \theta_0) \\ &\quad - E\left((g(\beta_0^T X) - E(g(\beta_0^T X)|\beta_0^T X))g'(\beta_0^T X)J(\theta_0)^T X\right). \end{aligned} \quad (2.6)$$

In terms of (2.5) and (2.6), we can make a comparison with the classical least squares or likelihood. Asymptotically, our approach makes the equation to have an extra term $E\left((g(\beta_0^T X) - (E(Y|\beta_0^T X)))g'(\beta_0^T X)J(\theta_0)^T X\right)$ at the true value of β_0 . This term does not come up in the classical least squares because by the model structure, this term equals zero at population level, and thus, in classical framework, we do not bother ourself to “estimate” it. More importantly, from (2.6), we can see easily that $E\left((g(\beta_0^T X) - (E(Y|\beta_0^T X)))g'(\beta_0^T X)J(\theta_0)^T X\right)$ is non-positively correlated to $E\left(\varepsilon g'(\beta_0^T X)J(\theta_0)^T X\right)$. The correlation is actually between $E\left(\varepsilon g'(\beta_0^T X)J(\theta_0)^T X\right)$ and $-E\left(\varepsilon(\varepsilon|\beta_0^T X)g'(\beta_0^T X)J(\theta_0)^T X\right)$. This helps us attain smaller variance at sample level. The details are in the following.

2.2.2 The gain from estimating $E(Y|\beta^T X)$

In the above presentation we note that the conditional expectation function $E(Y|\beta^T X)$ is a nuisance parameter to be estimated. From the approximation of (2.6), if we can define an estimator $\hat{E}(Y|\beta^T X)$ of $E(Y|\beta^T X)$ that satisfies the following requirements, an asymptotically more efficient estimation of β_0 can be expected. First, the estimator can make the second term on the right hand side of (2.6) to be asymptotically negligible. Second, its derivative at $\beta_0^T X$, $\hat{E}'(Y|\beta_0^T X)$ converges to $g'(\beta_0^T X)$ at certain rate. Third, more importantly, an estimation of $\hat{E}(Y|\beta^T X)$ would create an extra “estimation” $\hat{E}(Y|\beta_0^T X)$ of $g(\beta_0^T X)$ so that the weighted sum of $g(\beta_0^T x_i) - \hat{E}(Y|\beta_0^T x_i)$ ’s is *non-positively correlated* to the weighted sum of ε_i ’s for the purpose of variance reduction. From the above (2.5) and (2.6), we can see that we do get an extra term about $-\hat{E}(\varepsilon|\beta_0^T X)$. Specifically, such an extra estimation is not negligible, that is, $\hat{E}(Y|\beta_0^T X) - g(\beta_0^T X) = \hat{E}(\varepsilon|\beta_0^T X) + (\hat{E}(g(\beta_0^T X)|\beta_0^T X) - g(\beta_0^T X))$ is not negligible. Technically, we will prove that $(\hat{E}(g(\beta_0^T X)|\beta_0^T X) - g(\beta_0^T X))$ is negligible. Thus, the gain we can have is from $\hat{E}(\varepsilon|\beta_0^T X)$. Without confusion, here $\hat{E}$ means estimation of conditional mean and of unconditional mean for its appearance in different places. Note that $\hat{E}(\varepsilon g'(\beta_0^T X)J(\theta_0)^T X)$ is asymptotically normal and helps us achieve the Fisher information. When $\hat{E}\left((g(\beta_0^T X) - \hat{E}(Y|\beta_0^T X))g'(\beta_0^T X)J(\theta_0)^T X\right) \approx -\hat{E}\left(\hat{E}(\varepsilon|\beta_0^T X)g'(\beta_0^T X)J(\theta_0)^T X\right)$ is *non-positively related* to $\hat{E}(\varepsilon g'(\beta_0^T X)J(\theta_0)^T X)$, we will have chance to have a smaller variance than the Fisher information. This is just the case with our approach. The covariance between these two terms is asymptotically equal to

$$-Cov := -E(g'(\beta_0^T X)^2 E(J(\theta_0)^T X|\beta_0^T X) E(J(\theta_0)X^T|\beta_0^T X)).$$

Regardless of some technical details for nonparametric estimation, this calculation can be easily justified from (2.5) and (2.6). Interestingly, We can also derive that $\hat{E}\left((g(\beta_0^T X) - \hat{E}(Y|\beta_0^T X))g'(\beta_0^T X)J(\theta_0)^T X\right)$ has a limiting variance-covariance ma-

trix equal to Cov . In other words, the joint distribution of

$$(\hat{E}(\varepsilon g'(\beta_0^T X) J(\theta_0)^T X), \hat{E}((g(\beta_0^T X) - \hat{E}(Y|\beta_0^T X))g'(\beta_0^T X) J(\theta_0)^T X))$$

is asymptotically normal with the covariance matrix

$$\begin{pmatrix} E(g'(\beta_0^T X)^2 J(\theta_0)^T X X^T J(\theta_0)) & -Cov \\ -Cov & Cov \end{pmatrix}.$$

Thus, the sum of these two terms is asymptotically normal with the variance-covariance matrix

$$\tilde{Q} = V - Cov.$$

We can also obtain it from (2.6). Therefore, an extra estimation $\hat{E}(Y|\beta^T X)$ of $E(Y|\beta^T X)$ automatically introduces an extra “estimation” $\hat{E}(Y|\beta_0^T X)$ of $E(Y|\beta_0^T X) = g(\beta_0^T X)$ that can help us achieve the reduction of variance.

By comparing the two sides of (2.6), the limiting variance-covariance matrix of $\theta - \theta_0$ would be $V^{-1}\tilde{Q}V^{-1}$ where

$$\tilde{Q} = E\left(g'(\beta_0^T X)^2 J(\theta_0)^T (X - E(X|\beta_0^T X))(X^T - E(X^T|\beta_0^T X))J(\theta_0)\right),$$

and recalling its definition

$$V = E\left(g'(\beta_0^T X)^2 J(\theta_0)^T X X^T J(\theta_0)\right).$$

It is clear that $V - \tilde{Q} = Cov$ is a non-negative semidefinite matrix and then $V^{-1}\tilde{Q}V^{-1}$ is smaller than or equal to V^{-1} . From this, and $\beta - \beta_0 \approx J(\theta_0)(\theta - \theta_0)$, we may obtain that the limiting variance-covariance matrix would be $J(\theta_0)V^{-1}\tilde{Q}V^{-1}J(\theta_0)^T$. This matrix is smaller than or equal to $J(\theta_0)V^{-1}J(\theta_0)^T$.

The above “super-efficiency” can also be found to have a root from estimation problems with nuisance parameters as we mentioned in Section 1. For instance, suppose that we have a model with two sets of parameters: β_0 , the parameters of interest; and λ , nuisance parameters. Piece (1982) found that an estimation with estimated λ can sometimes be more efficient than an “estimation” with the true value of λ . In our setting, we regard the conditional expectation $E(Y|\cdot)$ as a nuisance parameter that is actually a pseudo-nuisance parameter for the models, and the link function $g(\cdot)$ is regarded as its true value. In the classical methodologies, the true value is used in estimations, whereas in our method, an estimation of $E(Y|\cdot)$ is plugged in.

3 Two-stage estimation procedures

From the above explanations about the least squares and likelihood, we can see the intrinsic difference of our approach from the classical estimations. This motivates

us to use the following quasi-likelihood for the purpose of variance reduction:

$$SG(\beta) = \sum_{i=1}^n (y_i - \hat{E}(Y|\beta^T x_i)) g'(\beta^T x_i) x_i / v(x_i) I_n(x_i), \quad (3.1)$$

where $\hat{E}(Y|\beta^T X)$ is an estimator of $E(Y|\beta^T X)$, $I_n(x_i) = I\{\hat{f}_{\hat{\beta}}(\hat{\beta}^T x_i) > c_0\}$ for some positive value c_0 , and $\hat{f}$ and $\hat{\gamma}_0$ are respectively estimators of the density function of $\beta_0^T X$ and β_0 in (3.13) of Section 3 where β_0 is replaced by γ_0 , the direction of β_0 . We can see the details in Section 3 below. The truncation $I_n(x_i)$ is employed here for technical purpose to handle the boundary points particularly when we use local smoothing method to estimate the nonparametric regression function $E(Y|\beta^T X)$, see Xia, and Härdle(2006).

However, the above arguments are only feasible in the case where the forth assumptions stated in the beginning of this subsection satisfy. The constraint $\|\beta_0\| = 1$ is intrinsic for our approach because for general β , $E(Y|\beta^T X) = E(Y|c\beta^T X)$ for any constant c and then the uniqueness of solution β cannot be guaranteed. To deal with this identifiability problem, we in the following propose two-stage estimation procedures.

3.1 Re-parametrization of the parameter

We note that although β_0 is not identifiable in the above procedure, its direction $\beta_0/\|\beta_0\|$ can be so when we apply the idea described in the previous subsection. As such, we can either estimate the direction first or its scale $\|\beta_0\|$ first. Write $\alpha_0 = \|\beta_0\|$ and $\gamma_0 = \beta_0/\|\beta_0\|$. It is easy to see that γ_0 is identifiable when we rewrite the original model as $Y = E(Y|\gamma_0^T X) + \varepsilon$. We can work on estimating γ_0 by using a similar estimating equation of (3.1) and α_0 can be estimated by the classical quasi-likelihood. However, we note that γ_0 is on the boundary of the unit sphere surface and then we cannot directly derive the scores in the quasi-likelihood. To deal with this, a re-parametrization is necessary. A popular re-parametrization is the "remove-one-component" method on β as in Yu and Ruppert(2002) and then Wang, Xue, Zhu and Chong (2010) and Chang, Xue and Zhu (2010). Without loss of generality, we may assume that the true parameter γ_0 has a positive component, say $\gamma_{0r} > 0$ for $\gamma_0 = (\gamma_{01}, \dots, \gamma_{0p})^T$ and $1 \leq i \leq n$. For $\gamma = (\gamma_1, \dots, \gamma_p)^T$, let $\gamma^{(r)} = (\gamma_1, \dots, \gamma_{r-1}, \gamma_{r+1}, \dots, \gamma_p)^T$ be the $p-1$ dimensional parameter vector after removing the r th component γ_r in γ . We may write

$$\gamma = \gamma(\gamma^{(r)}) = (\gamma_1, \dots, \gamma_{r-1}, (1 - \|\gamma^{(r)}\|^2)^{1/2}, \gamma_{r+1}, \dots, \gamma_p)^T. \quad (3.2)$$

The true parameter $\gamma_0^{(r)}$ must satisfy the constraint $\|\gamma_0^{(r)}\|^2 < 1$. Thus, γ is infinitely differential in a neighborhood of $\gamma_0^{(r)}$, and the Jacobian matrix is

$$J(\gamma^{(r)}) = \frac{\partial \gamma}{\partial \gamma^{(r)}} = (\delta_1, \dots, \delta_p)^T, \quad (3.3)$$

where $\delta_s (1 \leq s \leq p)$ satisfy that $\delta_s = e_s$ for $1 \leq s < r$, $\delta_r = -(1 - \|\gamma^{(r)}\|^2)^{-1/2} \gamma^{(r)}$, $\delta_s = e_{s-1}$ for $r+1 \leq s \leq p$. Here e_s is a $p-1$ dimensional unit vector with sth component 1. For this re-parametrization, we can also prove that $J(\gamma^{(r)})$ is orthogonal to γ . However, the columns within $J(\gamma^{(r)})$ are not orthogonal. Let $A(\gamma^{(r)}) = (\gamma, J(\gamma^{(r)}))$. We can have

$$A(\gamma^{(r)})^T A(\gamma^{(r)}) = \begin{pmatrix} 1 & \mathbf{0}^T \\ \mathbf{0} & J(\gamma^{(r)})^T J(\gamma^{(r)}) \end{pmatrix}$$

although it is not a diagonal matrix. Also, we can easily prove that $A(\gamma^{(r)})$ is invertible, and its inverse is

$$\begin{aligned} A(\gamma^{(r)})^T &= \begin{pmatrix} 1 & \mathbf{0}^T \\ \mathbf{0} & J(\gamma^{(r)})^T J(\gamma^{(r)}) \end{pmatrix} A(\gamma^{(r)})^{-1}, \\ A(\gamma^{(r)}) &= (A(\gamma^{(r)})^T)^{-1} \begin{pmatrix} 1 & \mathbf{0}^T \\ \mathbf{0} & J(\gamma^{(r)})^T J(\gamma^{(r)}) \end{pmatrix}. \end{aligned} \quad (3.4)$$

An alternative is re-parametrization by the polar coordinate system. to simplify the presentation, we assume with no loss of generality that the p -th component of γ is positive. That is, letting $\theta = (\theta_1, \dots, \theta_{p-1})^T$ whose domain is the $(p-1)$ -dimensional subspace $(0, \pi)^{p-2} \times (0, \pi/2)$,

$$\gamma = \gamma(\theta) = \left(\prod_{i=1}^{p-1} \cos(\theta_i), \sin(\theta_1) \prod_{i=2}^{p-1} \cos(\theta_i), \sin(\theta_2) \prod_{i=3}^{p-1} \cos(\theta_i) \cdots, \sin(\theta_{p-1}) \right)^T, \quad (3.5)$$

where $\prod_{i=p}^{p-1} \cos(\theta_i)$ is defined as 1. Otherwise, $\sin(\theta_{p-1})$ will be the r -th component that is positive. The Jacobian matrix $J(\theta) = \partial\gamma(\theta)/\partial\theta$ is of a special structure: the i -th column is the derivative of $\gamma(\theta)$ about θ_i , in the first i components, $\sin(\theta_i)$ and $\cos(\theta_i)$ are respectively replaced by $\cos(\theta_i)$ and $-\sin(\theta_i)$, and the other components in the column are equal to zero because the corresponding components do not have θ_i . It is easy to prove that all the columns are orthogonal to each other. Furthermore, $J(\theta)$ is orthogonal to $\gamma(\theta)$. A brief justification can be done by induction. When $p = 2$, the conclusion is clearly true. Assume that when $p = m-1$ the conclusion is true. When $p = m$, $\gamma_m = (\cos(\theta_m) \gamma_{m-1}^T, \sin(\theta_m))^T$. For the derivative about θ_i with $i \leq m-1$,

$$\partial\gamma_m/\partial\theta_i = (\cos(\theta_m) \partial\gamma_{m-1}^T/\partial\theta_i, 0)^T$$

Then for any $1 \leq j < i$,

$$(\partial\gamma_m^T/\partial\theta_i)(\partial\gamma_m/\partial\theta_j) = (\partial\gamma_{m-1}^T/\partial\theta_i)(\partial\gamma_{m-1}/\partial\theta_j) \cos(\theta_m)^2 = 0.$$

When $i = m$, $\partial\gamma_m/\partial\theta_m = (\sin(\theta_m) \gamma_{m-1}^T, \cos(\theta_m))^T$, we have for any $j < m$

$$\begin{aligned} & (\partial\gamma_m^T/\partial\theta_j)(\partial\gamma_m/\partial\theta_m) \\ &= (\sin(\theta_m) \partial\gamma_{m-1}^T/\partial\theta_j, 0)(\cos(\theta_m) \gamma_{m-1}^T, -\sin(\theta_m))^T \\ &= \cos(\theta_m) \sin(\theta_m) (\partial\gamma_{m-1}^T/\partial\theta_j) \gamma_{m-1} = 0. \end{aligned}$$

But $A(\theta) := (\gamma(\theta), J(\theta))$ is not an orthogonal matrix although

$$A(\theta)^T A(\theta) = \begin{pmatrix} 1 & \mathbf{0}^T \\ \mathbf{0} & J(\theta)^T J(\theta) \end{pmatrix}.$$

is a diagonal matrix as not all elements are equal to 1. Also, we can easily prove that

$$A(\theta)^T = \begin{pmatrix} 1 & \mathbf{0}^T \\ \mathbf{0} & J(\theta)^T J(\theta) \end{pmatrix} A(\theta)^+, \quad A(\theta) = (A(\theta)^T)^+ \begin{pmatrix} 1 & \mathbf{0}^T \\ \mathbf{0} & J(\theta)^T J(\theta) \end{pmatrix}. \quad (3.6)$$

where A^+ is the Moore-Penrose inverse of matrix A in case A is not invertible. This will be useful in the later analysis.

We can see that the two re-parametrizations have some similar properties. But, the former is easier to compute and $A(\gamma^{(r)})$ is always invertible whereas the latter has nicer orthogonality structure. Throughout the rest of the present paper, we assume with no loss of generality that $A(\theta)$ is invertible in the following, θ can be either $\gamma^{(r)}$ in the former or θ in the latter.

3.2 Estimation procedures

Now we are in the position to present estimation procedures. Note that $E(Y|\gamma_0^T X) = g(\alpha_0 \gamma_0^T X)$. The derivative of $g(\alpha \gamma(\theta)^T X)$ about θ is $g'(\alpha \gamma(\theta)^T X) \alpha J(\theta)^T X$. Further, as the estimation will involve nonparametric smoothing, the boundary effect needs to be dealt with, we will in the estimating equation trim off some boundary points in the following procedures.

Procedure 1.

Step 1. Obtain an initial estimator of β_0 , $\hat{\beta}_I$ by the estimating equation of (2.1), and then let $\hat{\gamma}_I = \hat{\beta}_I / \|\hat{\beta}_I\|$. Check the values of all components of $\hat{\gamma}_I$. Select an r with $1 \leq r \leq p$ such that $|\hat{\gamma}_I^{(r)}| = \max_{1 \leq l \leq p} |\hat{\gamma}_I^{(l)}|$. As $\hat{\gamma}_I^{(r)}$ is not necessary to be positive, we then define $\hat{\alpha}_I = \text{sign}(\hat{\gamma}_I^{(r)}) \|\hat{\beta}_I\|$. As such, we can define the domain $\Gamma(\Theta)$ of $\gamma(\theta)$ with the constraint that the r th component of $\gamma(\theta)$ is positive.

Step 2. Estimate θ_0 by the solution $\hat{\theta}$ of

$$SG(\theta) = \sum_{i=1}^n (y_i - \hat{E}(Y|\gamma(\theta)^T x_i)) g'(\hat{\alpha} \gamma(\theta)^T x_i) J(\theta)^T x_i / v(x_i) \tilde{I}_n(x_i) = 0. \quad (3.7)$$

over the domain $\Gamma(\Theta)$, where $\tilde{I}_n(x_i)$ is a truncation function in (3.1).

Step 3. Obtain the final estimator of β as $\hat{\beta}_F = \hat{\alpha}_I \gamma(\hat{\theta})$.

Another procedure uses an iterative algorithm with one more new Step benefiting from the variance reduction estimation of γ above.

Procedure 2.

Step 1. Obtain an initial estimator of $\beta_0, \hat{\beta}_I$ by the estimating equation of (2.1), and then let $\hat{\gamma}_I = \hat{\beta}_I / \|\hat{\beta}_I\|$. Define $\hat{\alpha}_I = \|\hat{\beta}_I\|$.

Step 2. Estimate θ_0 by the solution $\hat{\theta}$ of

$$SG(\theta) = \sum_{i=1}^n (y_i - \hat{E}(Y|\gamma(\theta)^T x_i)) g'(\hat{\alpha}\gamma(\theta)^T x_i) J(\theta)^T x_i / v(x_i) \tilde{I}_n(x_i) = 0. \quad (3.8)$$

over all θ), where $\tilde{I}_n(x_i)$ is a truncation function in (3.1).

Step 3. Estimate α_0 by the solution $\hat{\alpha}_F$ of

$$G(\alpha) = \sum_{i=1}^n (y_i - g(\alpha\gamma(\hat{\theta})^T x_i)) g'(\alpha\gamma(\hat{\theta})^T x_i) \gamma(\hat{\theta})^T x_i / v(x_i) \tilde{I}_n(x_i) = 0. \quad (3.9)$$

Step 4. Obtain the final estimator of β as $\hat{\beta}_F = \hat{\alpha}_F \gamma(\hat{\theta})$.

REMARK 3.1. *The two procedures are different mainly for Step 1 and Step 3. When we assume that a component of γ is positive, the scalar α is then not necessary to be positive. To avoid this identification issue about sign, we define an $\hat{\alpha}_I$ with sign function in Step 1 of Procedure 1. But this is no need for Procedure 2 as after having an estimation of γ , we re-estimate the scalar α , with which, we can adoptively have the sign of α in the final estimation.*

REMARK 3.2. *Trimming boundary points off is a typical technique in nonparametric estimation when local smoothing is applied. We here simply use $\tilde{I}_n(x_i)$. Similar trimming can be found in Xia and Härdle (2006), and Xia, Härdle and Linton (2009) who used a smooth function instead of the indicator function. To achieve the results without such a function appeared in the limiting variance, that is, $\tilde{I}_n(x_i)$ goes to 1, we should let c_0 tend to zero as n goes to infinity. It is achievable as long as c_0 tends to zero at certain rate not too fast, see Xia and Härdle (2006), and Xia, Härdle and Linton (2009) for more details. Thus, we will not discuss the choice of c_0 in detail.*

3.3 Plug-in Estimation of $E(Y|\gamma^T X)$

In the estimation procedures above, we need a plug-in estimation for $E(Y|\gamma^T X)$. Here we consider local linear smoother. Suppose that $(x_i, y_i), 1 \leq i \leq n$ are independent identically distributed (iid) from model (1.2). To estimate nonparametrically $E(Y|\gamma^T X)$, the local linear smoother with the linear weighted functions $\{W_{ni}(z, \gamma, h); 1 \leq i \leq n\}$ is defined in the following. The local linear estimators of $E(Y|\gamma^T X)$ and its derivative are the pair (a, b) minimizing the weighted sum of squares (see Fan and Gijbels 1996)

$$\sum_{i=1}^n [y_i - a - b(x_i^T \gamma - z)]^2 K_h(x_i^T \gamma - z), \quad (3.10)$$

where $K_h(\cdot) = K(\cdot/h)/h$ with K being a symmetric kernel function on the real line and $h = h_n$ being a bandwidth.

Without confusion, we use the notation $\hat{g}(z; \gamma, h) := \hat{E}(Y|\gamma^T X = z)$. $\hat{g}(z; \gamma, h) = \hat{a}$ is the resulting estimator. Via a simple calculation, we have

$$\hat{g}(z; \gamma, h) = \sum_{i=1}^n W_{ni}(z; \gamma, h) y_i, \quad (3.11)$$

where, for $1 \leq i \leq n$,

$$W_{ni}(z; \gamma, h) = \frac{U_{ni}(z; \gamma, h)}{\sum_{i=1}^n U_{ni}(z; \gamma, h)} \quad (3.12)$$

with

$$\begin{aligned} U_{ni}(z; \gamma, h) &= [S_{n,2}(z; \gamma, h) - (x_i^T \gamma - z) S_{n,1}(z; \gamma, h)] K_h(x_i^T \gamma - z), \\ S_{n,r}(z; \gamma, h) &= \frac{1}{n} \sum_{i=1}^n (x_i^T \gamma - z)^r K_h(x_i^T \gamma - z), \quad r = 0, 1, 2. \end{aligned}$$

For the density function $f_\gamma(\gamma^T X)$, we can use the following estimator

$$\hat{f}_{\hat{\gamma}}(\hat{\gamma}^T x_i) = (nh^2)^{-1} \sum_{i=1}^n U_{ni}(\hat{\gamma}^T x_i; \hat{\gamma}, h), \quad (3.13)$$

and $\hat{\gamma} = \hat{\beta}_I / \|\hat{\beta}_I\|$.

4 Main results

By the classical quasi-likelihood for the GLM, we can have an initial estimator $\hat{\beta}_I$ of β_0 that is root- n consistent. It implies that $\hat{\gamma}_I$ is also root- n consistent to γ_0 . With this pilot estimation, we can then consider a neighborhood of $\hat{\gamma}_I$ which contains γ_0 to define our resulting estimator. Let $\mathcal{B}_n = \{\gamma : \|\gamma - \hat{\gamma}_I\| = Bn^{-1/2}\}$ where B is some positive constant.

THEOREM 4.1. *Suppose that conditions C1–C6 hold. Let the solution of (3.8) be $\gamma(\hat{\theta})$. Assume further that $f(x) > c_0$ and $f_\gamma(\gamma^T x) > c_0$ for all x in its support. We have*

$$\sqrt{n}(\gamma(\hat{\theta}) - \gamma_0) \xrightarrow{\mathcal{L}} N(0, J(\theta_0) \tilde{V}^{-1} Q_1 \tilde{V}^{-1} J(\theta_0)^T / \alpha_0^2),$$

where $Q_1 =: J(\theta_0)^T \tilde{Q} J(\theta_0) = E\{|\varepsilon|^2 g'(\beta_0^T X)^2 J(\theta_0)^T [X/v(X) - E(X/v(X)|\gamma_0^T X)] [X/v(X) - E(X/v(X)|\gamma_0^T X)]^T J(\theta_0)\}$, $\tilde{V} = E\{[g'(\beta_0^T X)]^2 J(\theta_0)^T X X^T / v(X) J(\theta_0)\}$.

REMARK 4.1. The above result is obtained under the condition $f(x) > c_0$ and $f_\gamma(\gamma^T x) > c_0$ for all x in its support for simplicity. When these conditions do not hold, in (3.8), $\tilde{I}_n(x_i) = I\{\hat{f}_{\hat{\gamma}}(\hat{\gamma}^T x_i) > c_0\}$ is not equal to 1, where, recalling its definition in (3.13) of the previous subsection, $\hat{f}_{\hat{\gamma}}(\hat{\gamma}^T x_i) = (nh^2)^{-1} \sum_{i=1}^n U_{ni}(\hat{\gamma}^T x_i; \hat{\gamma}, h)$, $\hat{\gamma} = \hat{\beta}_I / \|\hat{\beta}_I\|$. From the proof of Lemma 6.2, we can see that $\hat{f}_{\hat{\gamma}}(z)$ converges to a function $\mu_2 f_{\gamma_0}^2(z)$ where μ_2 to be specified in Appendix is related to the kernel function in local linear smoother. In the place of $X/v(X)$ we should use $X/v(X)\tilde{I}(X)$ where $\tilde{I}(X)$ is the limit of $\tilde{I}_n(X)$ as n tends to infinity. The above variance in the theorem can be regarded as the limit as c_0 go to zero at a certain rate. All the results below will be with $\tilde{I}_n(X) = 1$ for simplicity. Otherwise, the proof will be similar with more tedious computation, and the result will be substituted by $Q_1 = E\{|\varepsilon|^2 g'(\beta_0^T X)^2 J(\theta_0)^T [X\tilde{I}(X)/v(X) - E(X\tilde{I}(X)/v(X)|\gamma_0^T X)] [X\tilde{I}(X)/v(X) - E(X\tilde{I}(X)/v(X)|\gamma_0^T X)]^T J(\theta_0)\} =: J(\theta_0)^T \tilde{Q} J(\theta_0)$, and $\tilde{V} = E\{[g'(\beta_0^T X)]^2 J(\theta_0)^T X X^T \tilde{I}(X)/v(X) J(\theta_0)\}$ accordingly throughout this whole paper.

REMARK 4.2. For the single-index model, Wang, Xue, Zhu and Chong (2010) and Chang, Xue and Zhu (2010) also used estimating equations. However, their approaches are based on the least squares and the estimating equations are the derivatives of the least squares criterion. Thus, although their estimation is asymptotically more efficient than existing ones such as Härdle, Hall and Ichimura (1993) and Xia and Härdle (2006), it cannot have optimal properties what the quasi-likelihood can have. More importantly, when $v(X)$ is of a structure $v(\beta_0^T X)$ for which we will have discussions in Section 4, we cannot usually define consistent estimation from the estimating equations derived from weighted least squares, see Heyde(1997, page 4). Also, as in our setting, we can directly use the derivative $g'(\beta^T X)$ as g' is known. This is also different from the single-index model with unknown g' . The estimation procedure then has less nonparametric smoothing involved.

To make a comparison with the one derived by the classical quasi-likelihood, we give a proposition.

PROPOSITION 4.1. Let $\hat{\beta}$ is the quasi-likelihood estimator of β_0 , and let $\hat{\gamma} = \hat{\beta} / \|\hat{\beta}\|$, $\hat{\alpha} = \|\hat{\beta}\|$. Then the limiting variance of $\sqrt{n}(\hat{\alpha} - \alpha_0)$ is $\gamma_0^T V^{-1} \gamma_0$ and the limiting variance of $\sqrt{n}(\hat{\beta} / \|\hat{\beta}\| - \gamma_0)$ is $(\mathbf{0}_p, J(\theta_0))(A(\theta_0)^T V A(\theta_0))^{-1} (\mathbf{0}_p, J(\theta_0)^T) / \alpha_0^2$. This variance is greater than or equal to $J(\theta_0) \tilde{V}^{-1} Q_1 \tilde{V}^{-1} J(\theta_0)^T / \alpha_0^2$ in Theorem 4.1. Here $V = E[g'^2(\beta_0^T X) X X^T / v(X)]$ and $\mathbf{0}_p$ is a zero vector of p dimension.

REMARK 4.3. This proposition also shows that when the norm of β_0 is one, that is, $\beta_0 \equiv \gamma_0$, the limiting variance covariance matrix is smaller or equal to the quasi-Fisher information (or the Fisher information in the exponential distribution case). In general cases, this proposition helps us obtain the final estimator $\hat{\alpha}\gamma(\hat{\theta})$ with smaller limiting variance as follows.

THEOREM 4.2. Under the conditions of Theorem 4.1, when **Procedure 1** is applied, we have

$$\sqrt{n}(\hat{\alpha}\gamma(\hat{\theta}) - \beta_0) \xrightarrow{\mathcal{L}} N(0, A(\theta_0)WA(\theta_0)^T), \quad (4.1)$$

where $W = \begin{pmatrix} \gamma_0^T V^{-1} \gamma_0 & \mathbf{0}_{p-1}^T \\ \mathbf{0}_{p-1} & \tilde{V}^{-1} Q_1 \tilde{V}^{-1} \end{pmatrix}$, $\tilde{V}$ and V are respectively defined in Theorem 4.1 and Proposition 4.1.

For the estimator obtained by **Procedure 2**, we state the following theorem.

THEOREM 4.3. Under the conditions of Theorem 4.1, when **Procedure 2** is adopted, we have

$$\sqrt{n}(\hat{\alpha}_F \gamma(\hat{\theta}) - \beta_0) \xrightarrow{\mathcal{L}} N(0, A(\theta_0)W_1 A(\theta_0)^T), \quad (4.2)$$

where $W_1 = \begin{pmatrix} (\gamma_0^T V \gamma_0)^{-1} + \frac{\gamma_0^T V J(\theta) \tilde{V}^{-1} Q_1 \tilde{V}^{-1} J(\theta)^T V \gamma_0}{(\gamma_0^T V \gamma_0)^2} & \mathbf{0}_{p-1}^T \\ \mathbf{0}_{p-1} & \tilde{V}^{-1} Q_1 \tilde{V}^{-1} \end{pmatrix}$, and $W \geq W_1$.

The proof in the appendix shows that the first element of W is greater than or equal to the corresponding element of W_1 . Then $W \geq W_1$. This indicates that when we use the estimator $\hat{\gamma}$ as a plug-in for estimating α_0 , the resulting estimation does benefit from its smaller variance. This suggests that the estimation of α_0 directly from the classical quasi-likelihood is, at least asymptotically, also worse than the new method. We are now in the position to compare the matrices involved.

THEOREM 4.4. Let $V_2 = A(\theta_0)^T V A(\theta_0)$. Then $V^{-1} = A(\theta_0) V_2^{-1} A(\theta_0)^T$. We have
1. All the elements on the diagonal of W (or W_1) are smaller than or equal to the corresponding elements of V^{-1} .
2.

$$\text{trace}(V^{-1}) \geq \text{trace}(A(\theta_0)WA(\theta_0)^T) \text{ (or } \text{trace}(A(\theta_0)W_1A(\theta_0)^T)).$$

REMARK 4.4. In the proof in the Appendix, we can see that when $J(\theta_0)^T X/v(X)$ is uncorrelated to $(g'(\beta_0^T X))^2 \gamma_0^T X$, $V_2^{-1} \geq W (= W_1)$. Further, when a stronger assumption holds: $E(J(\theta_0)^T X/v(X) | \gamma_0^T X) = 0$, we have $Q_1 = \tilde{V}$. Thus, $V_2^{-1} = W (= W_1)$, and $V^{-1} = A(\theta_0)WA(\theta_0)^T$. This shows that the classical quasi-likelihood can be asymptotically equally efficient to the two-stage quasi-likelihood when $J(\theta_0)^T X$ is uncorrelated to $\gamma_0^T X$ in certain sense. This is the case when X follows a spherically symmetric distribution. Otherwise, the variance obtained by our method is smaller than that by the classical quasi-likelihood in the sense stated in the theorems. From these phenomenon, we can see that the estimation efficiency of the new method may benefit from the correlations among the predictors in certain sense.

5 Further discussions

As this is the first step towards a general idea of using semiparametric approaches to study parametric problems for the GLM, there are many potential issues worthy of further exploration.

1. In the previous sections, the conditional variance of ε given X is assumed to be known. In many GLM models, it is of a structure $v(\beta_0^T X)$ where $v(\cdot)$ is given up to a dispersion constant and β_0 is the parameter of interest in the regression function. In this case, when we use the quasi-likelihood to search for a solution, this unknown β_0 should be either replaced by an initial estimator or be estimated by the same quasi-likelihood. The estimating equation for the initial estimation $\hat{\beta}$ is

$$G(\beta) = \sum_{i=1}^n (y_i - g(\beta^T x_i)) g'(\beta^T x_i) x_i / v(\beta^T x_i) = 0, \quad (5.1)$$

assuming that v is given, and in **Procedure 1**, we change the estimating equation to obtain the solution of θ_0 by

$$SG(\gamma(\theta)) = \sum_{i=1}^n (y_i - \hat{E}(Y|\gamma(\theta)^T x_i)) g'(\hat{\alpha}\gamma(\theta)^T x_i) J(\theta)^T x_i / v(\hat{\alpha}\gamma(\theta)^T x_i) \tilde{I}_n(x_i) = 0, \quad (5.2)$$

or simply use $\hat{\beta}$ in $v(\cdot)$. From the motivation in Section 2 and the proof of Theorem 4.1, it is easy to see that the estimator of β_0 that is obtained by the modified **Procedure 1** with (5.2) is asymptotically not affected by any consistent estimation $\hat{\alpha}\gamma(\hat{\theta})$ (or $\hat{\beta}$) in $v(\hat{\alpha}\gamma(\hat{\theta})^T \cdot)$ (or $v(\hat{\beta}^T \cdot)$), and similarly for **Procedure 2** when we use

$$G(\alpha) = \sum_{i=1}^n (y_i - g(\alpha\gamma(\hat{\theta})^T x_i)) g'(\alpha\gamma(\hat{\theta})^T x_i) \gamma(\hat{\theta})^T x_i / v(\alpha\gamma(\hat{\theta})^T x_i) = 0. \quad (5.3)$$

Then the asymptotic properties are very similar to those in the previous theorems as if $v(\cdot)$ were given. Actually, the above can be more general with a general function $w(\beta^T X)$ in the lieu of $g'(\beta^T X)/v(\beta^T X)$, and the technical proof can be very similar.

Further, when $v(X)$ is of a single-index structure as $v(\alpha_0 \gamma_0^T X)$ with unknown function $v(\cdot)$, we can apply nonparametric smoothing to the squared residuals $(y_i - g(\hat{\beta}^T x_i))^2$ to construct, for any fixed γ , an estimation $\hat{v}(\hat{\alpha}\gamma^T X)$. This is possible because this function is the conditional expectation of ε^2 given $\gamma^T X$ where $\hat{\beta}$ is an initial estimator obtained by the classical quasi-likelihood as

$$G(\beta) = \sum_{i=1}^n (y_i - g(\beta^T x_i)) g'(\beta^T x_i) x_i = 0, \quad (5.4)$$

As is well known, this $\hat{\beta}$ is not asymptotically efficient, but still asymptotically normal and $\hat{v}(\cdot)$ is of a nonparametric convergence rate (see, Fan and Gijbels 1996). This helps to define our final estimation of β_0 . In **Procedure 1**, we change the estimating equation to obtain the solution of θ_0 by

$$SG(\gamma(\theta)) = \sum_{i=1}^n (y_i - \hat{E}(Y|\gamma(\theta)^T x_i)) g'(\hat{\alpha}\gamma(\theta)^T x_i) J(\theta)^T x_i / \hat{v}(\hat{\alpha}\gamma(\theta)^T x_i) \tilde{I}_n(x_i) = 0 \quad (5.5)$$

or in (5.5) we simply use $\hat{\beta}$ in lieu of $\hat{\alpha}\gamma(\theta)$ in the estimated variance function $\hat{v}(\hat{\alpha}\gamma(\theta)^T \cdot)$. In **Procedure 2**, we use

$$G(\alpha) = \sum_{i=1}^n (y_i - g(\alpha\gamma(\hat{\theta})^T x_i)) g'(\alpha\gamma(\hat{\theta})^T x_i) \gamma(\hat{\theta})^T x_i / \hat{v}(\alpha\gamma(\hat{\theta})^T x_i) = 0. \quad (5.6)$$

Again we can also derive the similar results in Section 2.

In the above two cases with given and unknown function $v(\cdot)$, the matrix Q_1 , compared with its form in Theorem 4.1, has a simpler structure because v is a function of β_0 : $Q_1 =: J(\theta_0)^T \tilde{Q} J(\theta_0) = E\{g'(\beta_0^T X)^2 / v(\beta_0^T X) J(\theta_0)^T [X - E(X|\gamma_0^T X)][X - E(X|\gamma_0^T X)]^T J(\theta_0)\}$.

2. The limiting variances are related to re-parametrization. Thus, it is also of interest to explore whether there is a re-parametrization so that the variances attain the minimum among all possible re-parametrization methods. It is noted that our results only need the orthogonality between γ and its Jacobin matrix. Thus any re-parametrization with this property can be used in deriving similar results.

3. A more fundamental issue is about the asymptotic efficiency in the new framework we consider. For the GLM, we introduce a nuisance parameter and regard the link function as its true value. This is for the purpose of introducing automatically an extra “estimation” of $g(\cdot)$ at the true value β_0 . When this “estimation” is non-positively correlated to the one that can achieve the Fisher information, the resulting estimation can have chance to be more efficient. This idea is general in principle. Hence, regardless of re-parametrization, could we have an optimal selection of extra “estimation” to achieve smallest possible variance? We guess that the variance we obtain by **Procedure 2** might be of some optimality property. More generally, for an estimation of parameter of interest β_0 , say, T_n , if we would be able to define an extra “estimation” $T_{n1}(\beta_0)$ at the true value of β_0 with non-positive correlation to $T_n - \beta_0$, the sum $(T_n - \beta_0) + T_{n1}(\beta_0)$ may have a smaller variance than that of $(T_n - \beta_0)$ when 2 time the covariance between them is, in absolute value, greater than the variance of $T_{n1}(\beta_0)$. As such, the key is how to find such an extra “estimation”. Our parameter space augmentation approach shows that it is possible at least for the GLM when we “intentionally” introduce a nuisance parameter into the model.

4. In this paper, we consider independent identically distributed cases. It may be readily extended to handle, say, cluster data and correlated data.

5. The advantage of the new method is its asymptotic efficiency. Compared with classical estimations, its computational cost should be more expensive. This is because it involves one-dimensional nonparametric estimation and then we may face possible computational inefficiency and instability with tuning parameter selection when compared with the classical quasi-likelihood. This deserves further studies for finite sample implementation.

6 Appendix

6.1 Conditions

To obtain the asymptotic behavior of the estimators, we first give the following conditions for technical purpose:

- C1.** (i) The distribution of X has a compact support set A .
(ii) The density function $f_\gamma(\cdot)$ of $\gamma^T X$ satisfies Lipschitz condition of order 1 for γ in a neighborhood of γ_0 . Further, $\gamma_0^T X$ has a bounded density function $f_{\gamma_0}(\cdot)$ on its support $\mathcal{T}$.
- C2.** (i) The function $g(\gamma^T X) = E(Y|\gamma^T X)$ has two bounded and continuous derivatives.
(ii) Let $l(z) = E(X/v(X)|\gamma_0^T X = z)$, and $l_s(\cdot)$ is the s -th component of $l(\cdot)$, $1 \leq s \leq p$. $l_s(\cdot)$ satisfies Lipschitz condition of order 1.
(iii) $Cov(X/v(X)|\gamma_0^T X = z)$ exists, $\max_{1 \leq s \leq p} E((X_s/v(X))^2|\gamma_0^T X = z) < c$.
- C3.** (i) The kernel K is a bounded, continuous and symmetric probability density function, satisfying

$$\int_{-\infty}^{\infty} u^2 K(u) du \neq 0, \quad \int_{-\infty}^{\infty} |u|^2 K(u) du < \infty;$$

- (ii) K satisfies Lipschitz conditions on $\mathbf{R}^1$.

C4. $E(\varepsilon|X) = 0, \text{var}(\varepsilon|X) = v(X) < \infty, E(\varepsilon^4|X) < \infty$.

C5. $h \rightarrow 0, nh^2/\log^2 n \rightarrow \infty, \limsup_{n \rightarrow \infty} nh^5 \leq c < \infty$.

C6. Both $V = E[g'^2(\beta_0^T X)XX^T/v(X)]$ and $\tilde{V} =: J(\theta_0)^T V J(\theta_0)$ are positive definite matrices, where $J(\theta_0)$ is the Jacobian matrix of $\partial\gamma/\partial\theta$ evaluated at $\theta = \theta_0$.

REMARK 6.1. *The Lipschitz condition and the derivatives in C1 and C2 are standard smoothing conditions. It is worth noticing that unlike other references, we do not bound the density function of $X^T\beta_0$ from zero. This is because when we use a truncation constant c_0 , we can ensure the truncated density, and then the denominators of $\hat{g}(z; \gamma_0, h)$ and $\hat{g}'(z; \gamma_0, h)$ are bounded away from zero. See Xia and Härdle (2006) as reference. C3 means that the kernel for smoothing is of second order. C4 is a standard condition on the error term. C6 ensures that the limiting variance for the estimator $\gamma(\hat{\theta})$ exists.*

6.2 Proofs

As the following lemmas are very similar to those of Wang, Xue, Zhu and Chong (2010), or Chang, Xue and Zhu (2010), we will only present the main steps of proofs. A relevant reference is Zhu and Xue (2006). The main differences from existing ones in these references are with different estimating equations and estimations involved.

LEMMA 6.1. *(Wang, Xue, Zhu and Chong 2010). Let $\xi_1(x, \gamma), \dots, \xi_n(x, \gamma)$ be a sequence of random variables. Denote $f_{x, \gamma}(V_i) = \xi_i(x, \gamma)$ for $i = 1, \dots, n$, where $V_1, \dots, V_n$ be a sequence of random variables, and $f_{x, \gamma}$ is a function on $\mathcal{A}_n$, where $\mathcal{A}_n = \{(x, \gamma) : (x, \gamma) \in A \times R^p, \|\gamma - \gamma_0\| \leq cn^{-1/2}\}$ and $c > 0$ is a constant. Assume that $f_{x, \gamma}$ satisfies*

$$\frac{1}{n} \sum_{i=1}^n |f_{x, \gamma}(V_i) - f_{x^*, \gamma^*}(V_i)| \leq cn^\alpha (\|\gamma - \gamma^*\| + \|x - x^*\|) \quad (\text{A.1})$$

for some constants x^*, γ^* , $a > 0$ and $c > 0$. Let $\varepsilon_n > 0$ depend only on n . If

$$P \left\{ \left| \frac{1}{n} \sum_{i=1}^n \xi_i(x, \gamma) \right| > \frac{1}{2} \varepsilon_n \right\} \leq \frac{1}{2} \quad (\text{A.2})$$

for $(x, \gamma) \in \mathcal{A}_n$, then we have

$$\begin{aligned} & P \left\{ \sup_{(x, \gamma) \in \mathcal{A}_n} \left| \frac{1}{n} \sum_{i=1}^n \xi_i(x, \gamma) \right| > \frac{1}{2} \varepsilon_n \right\} \\ & \leq c_1 n^{2pa} \varepsilon_n^{-2p} E \left\{ \sup_{(x, \gamma) \in \mathcal{A}_n} 2 \exp \left(\frac{-n^2 \varepsilon_n^2 / 128}{\sum_{i=1}^n \xi_i^2(x, \gamma)} \right) \wedge 1 \right\}, \end{aligned} \quad (\text{A.3})$$

where $c_1 > 0$ is a constant.

LEMMA 6.2. *Suppose that conditions C1, C2 and C3(i) hold. If $h = cn^{-a}$ for any*

$0 < a < 1/2$ and some constants $c > 0$, then for $i = 1, \dots, n$, we have

$$E[g(\beta_0^T x_j) - \sum_{i=1, i \neq j}^n W_{ni}(\gamma_0^T x_j; \gamma_0, h)g(\beta_0^T x_i)]^2 = O(h^4), \quad (\text{A.4})$$

$$E[g(\alpha_0 \gamma^T x) - \sum_{i=1, i \neq j}^n W_{ni}(\gamma^T x; \gamma, h)g(\alpha_0 \gamma^T x_i)]^2 = O(h^4), \quad (\text{A.5})$$

$$E \left[\sum_{i=1}^n W_{nj}(\gamma_0^T x_i; \gamma_0)g'(\beta_0^T x_i)l_s(\gamma_0^T x_i) - g'(\beta_0^T x_j)l_s(\gamma_0^T x_j) \right]^2 = O(\sqrt{h}), \quad (\text{A.6})$$

where l_s is defined in Condition C2.

Proof. The basic arguments of proof are from Wang, Xue, Zhu and Chong (2010), and it is very similar with Lemma 5.2 in Chang, Xue and Zhu (2010). We then provide their main steps. We prove the first conclusion and the others can be proven similarly. Denote $z_i = \gamma_0^T x_i$, $\tilde{z}_i = \beta_0^T x_i$, replacing $S_{n,r}(\gamma_0^T x_i; \gamma_0, h)$ and $U_{nj}(\gamma_0^T x_i; \gamma_0, h)$ by $S_{n,r}(z_i)$ and $U_{nj}(z_i)$ respectively for simplicity. We have

$$g(\tilde{z}_j) - \sum_{i=1}^n W_{ni}(z_j)g(\tilde{z}_i) = \frac{\sum_{i=1}^n U_{ni}(z_j)[g(\tilde{z}_j) - g(\tilde{z}_i)]}{\sum_{i=1}^n U_{ni}(z_j)}. \quad (\text{A.7})$$

Let $E_{z_i}[\cdot]$ denote the conditional expectation given z_i . Denote $T_n = O_r(a_n)$ if $E|T_n|^r = O(a_n^r)$. Using Cauchy-Schwarz Inequality, we can easily obtain

$$O_r(a_n)O_r(b_n) = O_{r/2}(a_n b_n), \quad (\text{A.8})$$

$$T_n = E_{z_i}[T_n] + O_r((E|T_n - E_{z_i}[T_n]|^4)^{1/r}). \quad (\text{A.9})$$

From condition C1(ii) we know $M_{f_{\gamma_0}} = \sup_t f_{\gamma_0}(t) < \infty$, and there exists a constant $L > 0$ such that for any real y and t , $|f_{\gamma_0}(y) - f_{\gamma_0}(t)| < L|y - t|$. Using this facts. when n large enough, we can obtain that for $i = 1, \dots, n$,

$$E_{z_i}[S_{n,r}(z_i)] = h^r \mu_r f_{\gamma_0}(z_i)(1 + O(h)), \quad r = 0, 1, 2 \quad (\text{A.10})$$

where $\mu_r = \int_{-\infty}^{\infty} u^r K(u)du$, $r = 0, 1, 2$, $\mu_0 = 1$ and $\mu_1 = 0$.

By the inequality of sum of independent random variables(see Petrov, 1995), we obtain that

$$\begin{aligned} & E\{|S_{n,r}(z_i) - E_{z_i}S_{n,r}(z_i)|^4\} = E\{E_{z_i}|S_{n,r}(z_i) - E_{z_i}S_{n,r}(z_i)|^4\} \\ & \leq cn^{-4}(n-1)h^{4r-3} \int_{-\infty}^{\infty} |u^r K(u)|du(Ef_{\gamma_0}(z_i) + Lh) \\ & \quad + cn^{-4}E[2(n-1)h^{2r-3} \int_{-\infty}^{\infty} u^{2r} K^2(u)du(f_{\gamma_0}(z_i) + Lh)] \\ & = O(n^{-3}h^{4r-3}) + O(n^{-2}h^{2r-2}). \end{aligned} \quad (\text{A.11})$$

This together with (A.9) and (A.10) proves that

$$\begin{aligned} S_{n,r}(z_i) &= E_{z_i}[S_{n,r}(z_i)] + O_r(h^r(nh)^{-1/2}) \\ &= \mu_r h^r f_{\gamma_0}(z_i)(1 + O_4(h + (nh)^{-1/2})). \end{aligned} \quad (\text{A.12})$$

By (A.8) and (A.12), we have

$$\begin{aligned} \frac{1}{n} \sum_{i=1}^n U_{ni}(z_j) &= S_{n,0}(z_j)S_{n,2}(z_j) - S_{n,1}^2(z_j) \\ &= \mu_2 h^2 f_{\gamma_0}^2(z_j)(1 + O_4(h + (nh)^{-1/2})). \end{aligned} \quad (\text{A.13})$$

Let $U_n(z) = (nh^2)^{-1} \sum_{i=1}^n U_{ni}(z)$ and $U(z) = \mu_2 f_{\gamma_0}^2(z)$. Using Lemma 6.1, (A.13) and Borel-Cantelli's Lemma, we can prove[refer to Wang, Xue, Zhu and Chong (2010)]

$$\sup_{z \in \mathcal{T}} |U_n(z) - U(z)| \rightarrow 0, \quad a.s. \quad (\text{A.14})$$

From condition C1 we know $\inf_{z \in \mathcal{T}} f_{\gamma_0}(z) \geq c > 0$. thus, when n is large enough,

$$\inf_{z \in \mathcal{T}} |U_n(z)| \geq \inf_{z \in \mathcal{T}} |U(z)| - \sup_{z \in \mathcal{T}} |U_n(z) - U(z)| > \mu_2 c^2 / 2 > 0, \quad a.s. \quad (\text{A.15})$$

Write $H(\tilde{z}_i, \tilde{z}_j) = g(\tilde{z}_j) - g(\tilde{z}_i) + g'(\tilde{z}_j)(z_i - z_j)\alpha_0$. Noting that $\sum_{i=1}^n U_{ni}(z_j)(z_i - z_j) = 0$, we have

$$\begin{aligned} &\sum_{i=1}^n U_{ni}(z_j)(g(\tilde{z}_j) - g(\tilde{z}_i)) = \sum_{i=1}^n H(\tilde{z}_i, \tilde{z}_j)U_{ni}(z_j) \\ &= \sum_{i=1}^n H(\tilde{z}_i, \tilde{z}_j)K_h(z_i - z_j)S_{n,2}(z_j) \\ &\quad - \sum_{i=1}^n H(\tilde{z}_i, \tilde{z}_j)(z_i - z_j)K_h(z_i - z_j)S_{n,1}(z_j). \end{aligned} \quad (\text{A.16})$$

Similar as the proof of (A.12) for $r = 0, 1$, we have

$$\begin{aligned} &\frac{1}{nh^{2+r}} \sum_{i=1}^n H(\tilde{z}_i, \tilde{z}_j)(z_i - z_j)^r K_h(z_i - z_j) \\ &= h^{-2-r} E_{z_j}[H(\tilde{z}_i, \tilde{z}_j)(z_1 - z_j)^r K_h(z_1 - z_j)] + o_4(1) \\ &=: d_{nr} + o_4(1), \quad 2 \leq j \leq n, \end{aligned} \quad (\text{A.17})$$

and $|d_{nr}| \leq c \int |u|^{2+r} K(u) du (f_{\gamma_0}(Z_j) + O(h)) = O(1)$. This together with (A.12), (A.16) and (A.17) proves

$$\sum_{i=1}^n U_{ni}(z_j)(g(\tilde{z}_j) - g(\tilde{z}_i)) = nh^4 \mu_2 f_{\gamma_0}(Z_j) d_{n0} + o_2(nh^4).$$

Thus, combining again (A.15), we conclude

$$\begin{aligned} & E \left| \frac{\sum_{i=1}^n U_{ni}(z_j)(g(\tilde{z}_j) - g(\tilde{z}_i))}{\sum_{i=1}^n U_{ni}(z_j)} \right|^2 \\ & \leq c(nh^2)^{-2} E \left| \sum_{i=1}^n U_{ni}(z_j)(g(\tilde{z}_j) - g(\tilde{z}_i)) \right|^2 = O(h^4). \end{aligned} \quad (\text{A.18})$$

(A.4) now follows from (A.7) and (A.17). #

LEMMA 6.3. *Under the conditions of Lemma 6.2, we have*

$$E \left\{ \sum_{i=1}^n W_{ni}^2(\gamma^T x; \gamma, h) \right\} = O((nh)^{-1}), \quad (\text{A.19})$$

$$\begin{cases} E \{ W_{ni}^2(\gamma_0^T x_i; \gamma_0, h) \} = O((nh)^{-2}) \\ E \left\{ \sum_{i=1, i \neq j}^n W_{ni}^2(\gamma_0^T x_j; \gamma_0, h) \right\} = O((nh)^{-1}) \end{cases} \quad (\text{A.20})$$

Proof. The proof of Lemma 6.3 is similar as the proof in Lemma 6.2, hence, we omit it. #

LEMMA 6.4. *Suppose that conditions C1-C4 and C5(i) hold. We then have*

$$\sup_{(x, \gamma) \in \mathcal{A}_n} |g(\beta_0^T x) - \hat{g}(\gamma^T x; \gamma, h)| = O_p((nh/\log n)^{-1/2}). \quad (\text{A.21})$$

Proof. Write $\tilde{g}(x_i, \varepsilon_i) = g(\beta_0^T x) - g(\beta_0^T x_i) - \varepsilon_i$, $i = 1, \dots, n$. We have

$$g(\beta_0^T x) - \hat{g}(\gamma^T x; \gamma, h) = \sum_{i=1}^n W_{ni}(\gamma^T x; \gamma, h) \tilde{g}(x_i, \varepsilon_i). \quad (\text{A.22})$$

Let $\xi_i(x, \gamma) = n(nh/\log n)^{1/2} W_{ni}(\gamma^T x; \gamma, h) \tilde{g}(x_i, \varepsilon_i)$, $f_{x, \gamma}(V_i) = \xi_i(x, \gamma)$, $V_i = (x_i, \varepsilon_i)$, $i = 1, \dots, n$. Now we test and verify (A.1) and (A.2) in Lemma 6.1. A simple calculation yields (A.1). For (A.2), by Lemma 6.2 and Lemma 6.3(A.19) and noting that $\sup_{(x, \gamma) \in \mathcal{A}_n} |g(\alpha_0 \gamma^T x) - g(x^T \beta_0)| = O(n^{-1/2})$, $\gamma = \beta/\|\beta\|$, we have

$$\begin{aligned} & E[g(\beta_0^T x) - \hat{g}(\gamma^T x; \gamma, h)]^2 \\ & = E \left[\sum_{i=1}^n W_{ni}(\gamma^T x; \gamma, h) \tilde{g}(x_i, \varepsilon_i) \right]^2 \\ & \leq cE[g(\beta_0^T x) - \sum_{i=1}^n W_{ni}(\gamma^T x; \gamma, h)g(\beta_0^T x_i)]^2 \\ & \quad + cE \left[\sum_{i=1}^n W_{ni}^2(\gamma^T x; \gamma, h) \right] + O(n^{-1}) \\ & \leq ch^4 + c(nh)^{-1}. \end{aligned} \quad (\text{A.23})$$

Given a $M > 0$, by Chebbychev's inequality and (A.23), we have

$$\begin{aligned}
P \left\{ \left| \frac{1}{n} \sum_{i=1}^n \xi_i(x, \gamma) \right| > \frac{1}{2} M \right\} &\leq 4M^{-2} E \left[\frac{1}{n} \sum_{i=1}^n \xi_i(x, \gamma) \right]^2 \\
&\leq 4M^{-2} nh(\log n)^{-1} E \left[\sum_{i=1}^n W_{ni}(x^T \gamma; \gamma, h) \tilde{g}(X_i, \varepsilon_i) \right]^2 \\
&\leq cM^{-2}(cnh^5 + c(\log n)^{-1}).
\end{aligned} \tag{A.24}$$

Therefore, from condition C5, we can choose M large enough so that the right hand side of (A.24) is less than or equal to $\frac{1}{2}$. Hence, (A.2) is satisfied. We now can use (A.3) of Lemma 6.1 to get (A.21). By (A.19), we obtain that

$$\begin{aligned}
n^{-2} \sum_{i=1}^n E \xi_i^2(x, \gamma) &= nh(\log n)^{-1} \sum_{i=1}^n E[W_{ni}(\gamma^T x; \gamma, h) \tilde{g}(x_i, \varepsilon_i)]^2 \\
&\leq cnh(\log n)^{-1} \sum_{i=1}^n E W_{ni}^2(\gamma^T x; \gamma, h) \\
&\leq c(\log n)^{-1}.
\end{aligned}$$

This implies that $n^{-2} \sum_{i=1}^n \xi_i^2(x, \gamma) = O_p((\log n)^{-1})$. Hence, from Lemma 6.1 we have

$$P \left\{ \sup_{(x, \gamma) \in \mathcal{A}_n} \left| \frac{1}{n} \sum_{i=1}^n \xi_i(x, \gamma) \right| > \frac{1}{2} M \right\} \leq cn^{2pa} M^{-2p} \exp(-cM^2 \log n).$$

The right hand side of the above formula to zero when M is large enough. There, (A.21) is shown. #

LEMMA 6.5. *Suppose that conditions C1-C6 are satisfied. Then we have*

$$\sup_{\theta \in \mathcal{B}^*} \|R(\theta) - U(\theta_0) + nV_1(\theta - \theta_0)\| = o_p(\sqrt{n}), \tag{A.25}$$

where $\mathcal{B}^* = \{\theta : \|\theta - \theta_0\| \leq cn^{-1/2}\}$, for a constants $c > 0$, V_1 is defined in condition C6, and

$$R(\theta) = \sum_{i=1}^n [y_i - \hat{g}(\gamma(\theta)^T x_i; \theta, h)] g'(\hat{\alpha} \gamma(\theta)^T x_i) J(\theta)^T x_i / v(x_i) \tag{A.26}$$

$$U(\theta_0) = \sum_{i=1}^n \varepsilon_i g'(\beta_0^T x_i) J(\theta_0)^T [x_i / v(x_i) - E(X/v(X) | \gamma_0^T x_i)]. \tag{A.27}$$

as our denotation in section 3, $\beta_0 = \alpha_0 \gamma_0$, $\gamma_0 = \gamma(\theta_0)$, and $\hat{\alpha}$ is a consistent estimate of α_0 in section 3.

Proof. Separating $R(\theta)$, we have

$$\begin{aligned}
R(\theta) &= \sum_{i=1}^n \varepsilon_i g'(\beta_0^T x_i) J^T(\theta) [x_i/v(x_i) - E(x_i/v(x_i)|\gamma_0^T x_i)] \\
&+ \sum_{i=1}^n \varepsilon_i [g'(\hat{\alpha}\gamma(\theta)^T x_i) - g'(\alpha_0\gamma_0^T x_i)] J^T(\theta) x_i/v(x_i) \\
&- \sum_{i=1}^n g'(\beta_0^T x_i) J^T(\theta) x_i/v(x_i) [\hat{g}(\gamma(\theta)^T x_i; \theta, h) - \hat{g}(\gamma_0^T x_i; \gamma_0, h)] \\
&- \sum_{i=1}^n g'(\beta_0^T x_i) J^T(\theta) \{x_i/v(x_i) [\hat{g}(\gamma_0^T x_i; \gamma_0, h) - g(\beta_0^T x_i)] - \varepsilon_i l(\gamma_0^T x_i)\} \\
&- \sum_{i=1}^n [\hat{g}(\gamma(\theta)^T x_i; \theta, h) - g(\beta_0^T x_i)] [g'(\hat{\alpha}\gamma(\theta)^T x_i) - g'(\alpha_0\gamma_0^T x_i)] J^T(\theta) x_i/v(x_i) \\
&=: R_1(\theta) + R_2(\theta) - R_3(\theta) - R_4(\theta) - R_5(\theta), \tag{A.28}
\end{aligned}$$

where $l(\gamma_0^T X) = E(X/V(X)|\gamma_0^T X)$ which is defined in C2. $R_1(\theta)$ can be written as

$$\begin{aligned}
R_1(\theta) &= \sum_{i=1}^n \varepsilon_i g'(\alpha_0\gamma(\theta_0)^T x_i) J(\theta_0)^T [x_i/v(x_i) - E(X/v(X)|\gamma_0^T x_i)] \\
&+ \sum_{i=1}^n \varepsilon_i g'(\alpha_0\gamma(\theta_0)^T x_i) (J(\theta) - J(\theta_0))^T [x_i/v(x_i) - E(X/v(X)|\gamma_0^T x_i)]
\end{aligned}$$

Note that $\|J(\theta) - J(\theta_0)\| = O_p(n^{-1/2})$, for all $\theta \in \mathcal{B}^*$, then by the law of large numbers, we have

$$\sup_{\theta \in \mathcal{B}^*} \|R_1(\theta) - U(\theta_0)\| = o_p(\sqrt{n}). \tag{A.29}$$

For $R_2(\theta)$, as $\|\gamma(\theta) - \gamma(\theta_0)\| = O_p(n^{-1/2})$, $\|\hat{\alpha}\gamma(\theta) - \alpha_0\gamma(\theta_0)\| = O_p(n^{-1/2})$, for all $\theta \in \mathcal{B}^*$. By the Taylor expansion of $g'(\hat{\alpha}\gamma(\theta)^T x_i) - g'(\alpha_0\gamma(\theta_0)^T x_i)$, and the law of large numbers, we have

$$\sup_{\theta \in \mathcal{B}^*} \|R_2(\theta)\| = o_p(\sqrt{n}) \tag{A.30}$$

By Taylor expansion of $\hat{g}$, we have for $R_3(\theta)$

$$\begin{aligned}
R_3(\theta) &= \sum_{i=1}^n g'(\alpha_0\gamma(\theta_0)^T x_i) J(\theta)^T x_i/v(x_i) [\hat{g}(\gamma(\theta)^T x_i; \theta, h) - \hat{g}(\gamma(\theta_0)^T x_i; \theta_0, h)] \\
&= \sum_{i=1}^n g'(\alpha_0\gamma(\theta_0)^T x_i) J(\theta_0)^T x_i/v(x_i) x_i^T [\hat{g}'(\gamma(\theta_0)^T x_i; \theta_0, h)(\gamma(\theta) - \gamma(\theta_0))] + o_p(\sqrt{n})
\end{aligned}$$

where $\hat{g}(\gamma(\theta_0)^T x_i; \theta_0, h) = \hat{E}(Y|\gamma(\theta_0)^T x_i)$. Known that $\hat{E}'(Y|\gamma(\theta_0)^T x_i) \xrightarrow{p} E'(Y|\gamma(\theta_0)^T x_i)$, and actually $E'(Y|\gamma(\theta_0)^T x_i) = \frac{\partial g(\beta_0^T X)}{\partial (\gamma(\theta_0)^T X)}|_{\gamma(\theta_0)^T x_i} = \alpha_0 g'(\alpha_0 \gamma(\theta_0)^T x_i)$. So, we obtain that

$$R_3(\theta) = \alpha_0 \sum_{i=1}^n [g'(\beta_0^T x_i)]^2 J(\theta_0)^T x_i / v(x_i) x_i^T J(\theta_0) (\theta - \theta_0) + o_p(\sqrt{n})$$

by Weak Law of Large Numbers, we can derive

$$\sup_{\theta \in \mathcal{B}^*} \|R_3(\theta) - nV_1(\theta - \theta_0)\| = o_p(\sqrt{n}) \quad (\text{A.31})$$

where V_1 is defined in C6.

For $R_4(\theta)$, using the similar method as in Lemma A.5. of Chang, Xue and Zhu(2010), using our Lemma 6.2 and Lemma 6.3, write $R_4(\theta) = J^T(\theta)R_4^*(\theta)$. Let R_{4s}^* denote the s th component of $R_4^*(\theta)$, we can derive that

$$\begin{aligned} \frac{1}{n} E(R_{4s}^*)^2 &= \frac{1}{n} E \left(\sum_{i=1}^n g'(\beta_0^T x_i) \{x_{is}/v(x_i) [\hat{g}(\gamma_0^T x_i) - g(\beta_0^T x_i)] - \varepsilon_i l_s(\gamma_0^T x_i)\} \right)^2 \\ &\leq cn^{-1} E \left(\sum_{i=1}^n g'(\beta_0^T x_i) x_{is}/v(x_i) \left[\sum_{j=1}^n W_{nj}(\gamma_0^T x_i) g(\beta_0^T x_j) - g(\beta_0^T x_i) \right] \right)^2 \\ &\quad + cn^{-1} E \left(\sum_{i=1}^n g'(\beta_0^T x_i) [x_{is}/v(x_i) \sum_{j=1}^n W_{nj}(\gamma_0^T x_j) \varepsilon_j - \varepsilon_i l_s(\gamma_0^T x_i)] \right)^2 \\ &=: cn^{-1} E(R_{4s1}^*)^2 + cn^{-1} E(R_{4s2}^*)^2 \end{aligned} \quad (\text{A.32})$$

$$E(R_{4s1}^*)^2 \leq c \sum_{i=1}^n \left(E g'^2(\beta_0^T x_i) \left[\sum_{j=1}^n W_{nj}(\gamma_0^T x_i) g(\beta_0^T x_j) - g(\beta_0^T x_i) \right]^2 E((x_{is}/v(x_i))^2 | \gamma_0^T x_i) \right)$$

by C(iii) and Lemma 6.2, we have

$$E(R_{4s1}^*)^2 \leq cnh^4 \quad (\text{A.33})$$

For R_{4s2}^*

$$\begin{aligned} E(R_{4s2}^*)^2 &= \sum_{j=1}^n E \left(v(x_j) \left(\sum_{i=1}^n g'(\beta_0^T x_i) x_{is}/v(x_i) W_{nj}(\gamma_0^T x_i) - g'(\beta_0^T x_j) l_s(\gamma_0^T x_j) \right)^2 \right) \\ &\leq c \sum_{i=1}^n E \left(v(x_i) \left(\sum_{j=1}^n g'(\beta_0^T x_j) W_{ni}(\gamma_0^T x_j) l_s(\gamma_0^T x_j) - g'(\beta_0^T x_i) l_s(\gamma_0^T x_i) \right)^2 \right) \\ &\quad + c \sum_{i=1}^n E \left(v(x_i) \left(\sum_{j=1}^n g'(\beta_0^T x_j) W_{ni}(\gamma_0^T x_j) (x_{js}/v(x_j) - l_s(\gamma_0^T x_j)) \right)^2 \right). \end{aligned}$$

By Lemma 6.2, C(iii) and Lemma 6.3, we can obtain

$$E(R_{4s2}^*)^2 \leq cn\sqrt{h} + cn(nh)^{-1} \quad (\text{A.34})$$

Together with (A.33), (A.33) and (A.34) we get

$$\frac{1}{n}E(R_{4s2}^*)^2 \leq ch^4 + c\sqrt{h} + c(nh)^{-1} \rightarrow 0.$$

This implies

$$\sup_{\theta \in \mathcal{B}^*} \|R_4(\theta)\| = o_p(\sqrt{n}). \quad (\text{A.35})$$

For $R_5(\theta)$, by Taylor expansion to $g'(\cdot)$, together with $\|\hat{\alpha}\gamma(\theta) - \alpha_0\gamma(\theta_0)\| = O_p(n^{-1/2})$, for all $\theta \in \mathcal{B}^*$, we have

$$R_5(\theta) = \sum_{i=1}^n O_p(n^{-1/2})[\hat{g}(\gamma(\theta)^T x_i; \theta, h) - g(\beta_0^T x_i)]J^T(\theta)x_i/v(x_i).$$

By Lemma 6.4 and Condition C5, we obtain

$$\sup_{\beta^{(r)} \in \mathcal{B}^*} \|R_5(\beta^{(r)})\| = o_p(\sqrt{n}). \quad (\text{A.36})$$

Together with (A.29)- (A.36) we conclude the proof of Lemma 6.5. #

REMARK 6.2. When we consider (3.8) with $\tilde{I}_n(x_i)$, as $\|\tilde{I}_n(x_i) - I_n(x_i)\| \rightarrow 0$ can be proved, we can first substitute $\tilde{I}_n(x_i)$ with $I_n(x_i)$, and then use similar arguments as above, which will lead to Remark 4.1 right below Theorem 4.1.

Proof of Theorem 4.1 The existence of the estimator is easy to prove. As the estimating equation is similar with the one in Chang, Xue and Zhu(2010), and then the arguments are also very similar. We omit the proof here.

Then we show the asymptotic normality. $\gamma(\hat{\theta})$ is the solution of (3.8), that is, $R(\hat{\theta}) = 0$. By Lemma 6.1, we have

$$R(\hat{\theta}) = U(\theta_0) - nV_1(\hat{\theta} - \theta_0) + o_p(\sqrt{n}) = 0,$$

and hence

$$\sqrt{n}(\hat{\theta} - \theta_0) = V_1^{-1}n^{-1/2}U(\theta_0) + o_p(1).$$

It follows from (3.3) and (3.5) that

$$\gamma(\hat{\theta}) - \gamma(\theta_0) = J(\theta_0)(\hat{\theta} - \theta_0) + o_p(n^{-1/2}).$$

Thus, we have

$$\sqrt{n}(\gamma(\hat{\theta}) - \gamma(\theta_0)) = J(\theta_0)V_1^{-1}n^{-1/2}U(\theta_0) + o_p(1).$$

Theorem 4.1 now follows from Central Limit Theorems and Slutsky's Theorem. $\square$

Proof of Proposition 4.1 By the definition of $\hat{\alpha}_I$, it is easy to see that

$$\begin{aligned}\sqrt{n}(\hat{\alpha}_I - \alpha_0) &= \sqrt{n}(\hat{\beta}_I^T \hat{\beta}_I - \beta_0^T \beta_0) / (\|\hat{\beta}_I\| + \|\beta_0\|) \\ &= \sqrt{n}((\hat{\beta}_I - \beta_0)^T \gamma_0 + o(1))\end{aligned}$$

Then it is clear that the limiting variance is $\gamma_0^T V^{-1} \gamma_0$. For $\hat{\gamma} = \hat{\beta}_I / \|\hat{\beta}_I\|$, some elementary calculation yields that

$$\begin{aligned}\hat{\gamma} - \gamma_0 &= (\hat{\beta}_I / \|\hat{\beta}_I\| - \beta_0 / \|\beta_0\|) = (\hat{\beta}_I \|\beta_0\| - \beta_0 \|\hat{\beta}_I\|) / (\|\hat{\beta}_I\| \|\beta_0\|) \\ &= ((I_p - \gamma_0 \gamma_0^T)(\hat{\beta}_I - \beta_0)) / \|\beta_0\| + o(1/\sqrt{n}).\end{aligned}$$

From this presentation, we have the limiting variance:

$$(I_p - \gamma_0 \gamma_0^T) V^{-1} (I_p - \gamma_0 \gamma_0^T) / \alpha_0^2.$$

Note that $V^{-1} = A(\theta_0)(A(\theta_0)^T V A(\theta_0))^{-1} A(\theta_0)^T$, and $(I_p - \gamma_0 \gamma_0^T) A(\theta_0) = (\mathbf{0}_p, J(\theta_0))$. The result follows. $\square$

Proof of Theorem 4.2 As both $\hat{\alpha}_I$ and $\gamma(\hat{\theta})$ are respectively convergent to α_0 and γ_0 , it is easy to see that $\hat{\alpha}_I \gamma(\hat{\theta}) - \beta_0 = (\hat{\alpha}_I - \alpha_0) \gamma_0 + \alpha_0 (\gamma(\hat{\theta}) - \gamma_0) + o_p(1/\sqrt{n})$. From the standard proof for the asymptotic representation of $\hat{\beta}_I$ by the quasi likelihood, we have the following result. Noting that $\hat{\alpha} = \|\hat{\beta}_I\|$ and $\alpha_0 = \|\beta_0\|$, and together with the proof of Proposition 4.1, the estimator by the quasi-likelihood satisfies

$$\begin{aligned}\sqrt{n}(\|\hat{\beta}_I\| - \|\beta_0\|) &= \gamma_0^T \sqrt{n}(\hat{\beta}_I - \beta_0) + o_p(1) \\ &= \gamma_0^T V^{-1} \frac{1}{\sqrt{n}} \sum_{i=1}^n \varepsilon_i g'(\beta_0^T x_i) x_i / v(x_i) + o_p(1).\end{aligned}\quad (\text{A.37})$$

Then the application of Central Limit Theorems yields that it converges in distribution to a normal distribution with mean zero and variance $\gamma_0^T V^{-1} \gamma_0$. Further, from the proof of Theorem 4.1, we have

$$\begin{aligned}&\sqrt{n}(\gamma(\hat{\theta}) - \gamma_0) \\ &= J(\theta_0) V_1^{-1} \frac{1}{\sqrt{n}} \sum_{i=1}^n \varepsilon_i g'(\beta_0^T x_i) J(\theta_0)^T [x_i / v(x_i) - E(X/v(X) | \gamma_0^T x_i)] \\ &\quad + o_p(1).\end{aligned}\quad (\text{A.38})$$

Note that $A(\theta_0)^T \gamma_0 = (1, \mathbf{0}_{p-1}^T)^T$ and $A(\theta_0)^T J(\theta_0) = (\mathbf{0}_{p-1}, J(\theta_0)^T J(\theta_0))^T$. Thus, our estimator $\hat{\beta} = \hat{\alpha} \gamma(\hat{\theta})$ has

$$\begin{aligned} \sqrt{n}(\hat{\beta} - \beta_0) &= \sqrt{n}(A(\theta_0)^T)^{-1} A(\theta_0)^T (\hat{\beta} - \beta_0) \\ &= (A(\theta_0)^T)^{-1} \frac{1}{\sqrt{n}} \sum_{i=1}^n \varepsilon_i g'(\beta_0^T x_i) \left((1, \mathbf{0}_{p-1}^T)^T \gamma_0^T V^{-1} x_i / v(x_i) + \right. \\ &\quad \left. (\mathbf{0}_{p-1}, J(\theta_0)^T J(\theta_0))^T \tilde{V}^{-1} J(\theta_0)^T [x_i / v(x_i) - E(X/v(X) | \gamma_0^T x_i)] \right) \\ &\quad + o_p(1). \end{aligned} \tag{A.39}$$

Central Limit Theorems imply the asymptotic normality with mean zero and variance-covariance matrix

$$\begin{aligned} &(A(\theta_0)^T)^{-1} \begin{pmatrix} \gamma_0^T V^{-1} \gamma_0 & \mathbf{0}_{p-1}^T \\ \mathbf{0}_{p-1} & J(\theta_0)^T J(\theta_0) \tilde{V}^{-1} Q_1 \tilde{V}^{-1} J(\theta_0)^T J(\theta_0) \end{pmatrix} A(\theta_0)^{-1} \\ &= (A(\theta_0)^T)^{-1} \begin{pmatrix} 1 & \mathbf{0}_{p-1}^T \\ \mathbf{0}_{p-1} & J(\theta_0)^T J(\theta_0) \end{pmatrix} \begin{pmatrix} \gamma_0^T V^{-1} \gamma_0 & \mathbf{0}_{p-1}^T \\ \mathbf{0}_{p-1} & \tilde{V}^{-1} Q_1 \tilde{V}^{-1} \end{pmatrix} \begin{pmatrix} 1 & \mathbf{0}_{p-1}^T \\ \mathbf{0}_{p-1} & J(\theta_0)^T J(\theta_0) \end{pmatrix} A(\theta_0)^{-1} \\ &= A(\theta_0) W A(\theta_0)^T. \end{aligned}$$

The last equation holds because $(A(\theta_0)^T)^{-1} \begin{pmatrix} 1 & \mathbf{0}_{p-1}^T \\ \mathbf{0}_{p-1} & J(\theta_0)^T J(\theta_0) \end{pmatrix} = (A(\theta_0)^T)^{-1} A(\theta_0)^T A(\theta_0)$. The conclusion is proved. $\square$

Proof of Theorem 4.3. From the proof of Theorem 4.2, we only need to prove that $(\gamma_0^T V \gamma_0)^{-1} + \frac{\gamma_0^T V J(\theta_0) \tilde{V}^{-1} Q_1 \tilde{V}^{-1} J(\theta_0)^T V \gamma_0(\theta_0)}{(\gamma_0^T V \gamma_0)^2}$ is the limiting variance of the estimator $\hat{\alpha}_F$. From (2.2), we can derive that

$$\begin{aligned} &\frac{1}{\sqrt{n}} \sum_{i=1}^n \varepsilon_i g'(\alpha_0 \gamma_0^T x_i) \gamma_0^T x_i / v(x_i) \\ &= \gamma_0^T V \sqrt{n}(\hat{\alpha}_F \gamma(\hat{\theta}) - \beta_0) + o_p(1) \\ &= \gamma_0^T V \gamma_0 \sqrt{n}(\hat{\alpha}_F - \alpha_0) + \alpha_0 \gamma_0^T V \sqrt{n}(\gamma(\hat{\theta}) - \gamma_0) + o_p(1) \end{aligned}$$

Together with (A.38), we have

$$\begin{aligned} &\gamma_0^T V \gamma_0 \sqrt{n}(\hat{\alpha}_F - \alpha_0) \\ &= \frac{1}{\sqrt{n}} \sum_{i=1}^n \varepsilon_i g'(\beta_0^T x_i) \gamma(\theta_0)^T x_i / v(x_i) \\ &\quad - \gamma_0^T V J(\theta_0) \tilde{V}^{-1} \frac{1}{\sqrt{n}} \sum_{i=1}^n \varepsilon_i g'(\beta_0^T x_i) J(\theta_0)^T [x_i / v(x_i) - E(X/v(X) | \gamma_0^T x_i)] \end{aligned}$$

The right hand side is of a limiting variance as

$$\gamma_0^T V \gamma_0 + \gamma_0^T V J(\theta_0) \tilde{V}^{-1} Q_1 \tilde{V}^{-1} J(\theta_0)^T V \gamma_0 - 2 \gamma_0^T V J(\theta_0) \tilde{V}^{-1} J(\theta_0)^T Q_2 \gamma_0,$$

is the limiting variance-covariance matrix of $\gamma_0^T V \gamma_0 \sqrt{n}(\hat{\alpha}_F - \alpha_0)$, where $Q_2 = E(g^2(\beta_0^T X)(X/v(X) - E(X/v(X)|\gamma_0^T X))X^T)$. It is easy to prove that $C\gamma_0^T V J(\theta_0)\tilde{V}J(\theta_0)^T Q_2 \gamma_0 = 0$. The proof is completed. $\square$

Proof of Theorem 4.4. From the structure of V it is easy to see that V_2 can be written as

$$V_2 = A(\theta_0)^T V A(\theta_0) = \begin{pmatrix} \gamma_0^T V \gamma_0 & \gamma_0^T V J(\theta_0) \\ J(\theta_0)^T V \gamma_0 & J(\theta_0)^T V J(\theta_0) \end{pmatrix} =: \begin{pmatrix} V_{11} & V_{12} \\ V_{21} & \tilde{V} \end{pmatrix}.$$

Further, we have

$$V_2^{-1} = \begin{pmatrix} V_{11}^{-1} + V_{11}^{-2} V_{12} V_{22.1}^{-1} V_{21} & -V_{11}^{-1} V_{12} V_{22.1}^{-1} \\ -V_{22.1}^{-1} V_{21} V_{11}^{-1} & V_{22.1}^{-1} \end{pmatrix}$$

where $V_{22.1} = \tilde{V} - V_{21} V_{11}^{-1} V_{12}$. Note that $V_{21} V_{11}^{-1} V_{12}$ is a non-negative semidefinite and $\tilde{V}$ is positive definite. Thus, $V_{22.1} \leq \tilde{V}$ and $V_{22.1}^{-1} \geq \tilde{V}^{-1} \geq \tilde{V}^{-1} Q_1 \tilde{V}^{-1}$ as $Q_1 \leq \tilde{V}$. Note that $V^{-1} = A(\theta_0) V_2^{-1} A(\theta_0)^T$, and then $\gamma_0^T V^{-1} \gamma_0 = (V_2^{-1})_{11} = V_{11}^{-1} + V_{11}^{-2} V_{12} V_{22.1}^{-1} V_{21}$. These result in that $\text{trace}(V_2^{-1}) \geq \text{trace}(W)$. We then derive that, noting that $A(\theta_0)^T A(\theta_0) = \begin{pmatrix} 1 & \mathbf{0}_{p-1}^T \\ \mathbf{0}_{p-1} & J(\theta_0)^T J(\theta_0) \end{pmatrix}$ is a diagonal matrix,

$$\begin{aligned} \text{trace}(V^{-1}) &= \text{trace}(A(\theta_0) V_2^{-1} A(\theta_0)^T) \\ &= \text{trace}(V_2^{-1} A(\theta_0)^T A(\theta_0)) \\ &= V_{11}^{-1} + V_{11}^{-2} V_{12} V_{22.1}^{-1} V_{21} + \text{trace}(V_{22.1}^{-1} J(\theta_0)^T J(\theta_0)) \\ &\geq \gamma_0^T V^{-1} \gamma_0 + \text{trace}(\tilde{V}^{-1} Q_1 \tilde{V}^{-1} J(\theta_0)^T J(\theta_0)) \\ &= \text{trace}(A(\theta_0) W A(\theta_0)^T). \end{aligned}$$

For W_1 we have

$$\begin{aligned} &(\gamma_0^T V \gamma_0)^{-1} + \frac{\gamma_0^T V J(\theta_0) \tilde{V}^{-1} Q_1 \tilde{V}^{-1} J(\theta_0)^T V \gamma_0}{(\gamma_0^T V \gamma_0)^2} \\ &= V_{11}^{-1} + V_{12} \tilde{V}^{-1} Q_1 \tilde{V}^{-1} V_{21} V_{11}^{-2} \leq V_{11}^{-1} + V_{12} \tilde{V}^{-1} V_{21} V_{11}^{-2} \leq V_{11}^{-1} + V_{12} V_{22.1}^{-1} V_{21} V_{11}^{-2}. \end{aligned}$$

These result in that $\text{trace}(V_2^{-1}) \geq \text{trace}(W_1)$ and then

$$\text{trace}(V^{-1}) \geq \text{trace}(A(\theta_0) W_1 A(\theta_0)^T).$$

The proof is complete. $\square$
